

# Assessing the Complexity of Upgrading Software Modules

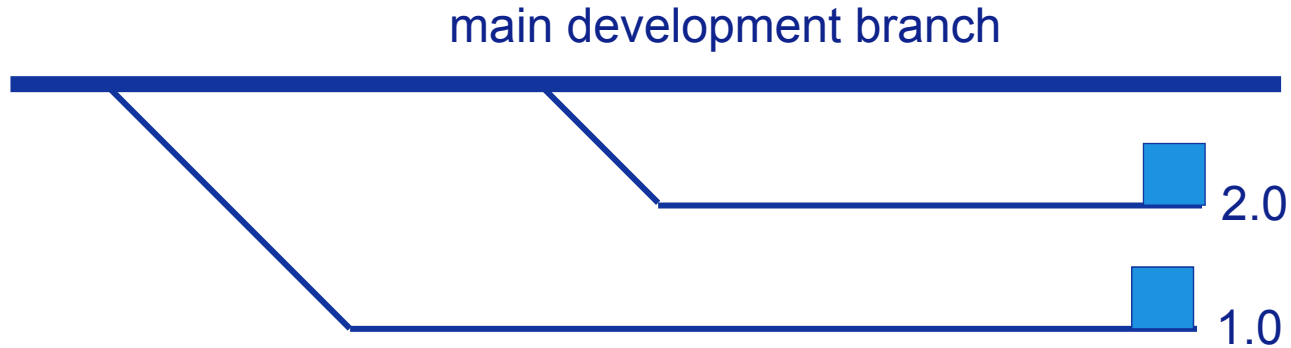

Bram Schoenmakers  
Alexander Serebrenik, Bogdan Vasilescu, Niels van den Broek, Istvan Nagy

October 15, 2013 | Koblenz, Germany

# Motivation

- Given a software system, continuously updated.
- **How to keep all branches in sync, including releases deployed at the customer?**

# Approach 1: write patch for one release, apply elsewhere

# Approach 2: use modules

1.3	1.2	1.2
1.2	1.1	1.2

Customer

1.3	1.2	1.2
1.2	1.1	1.2

Latest

## Motivation (2)

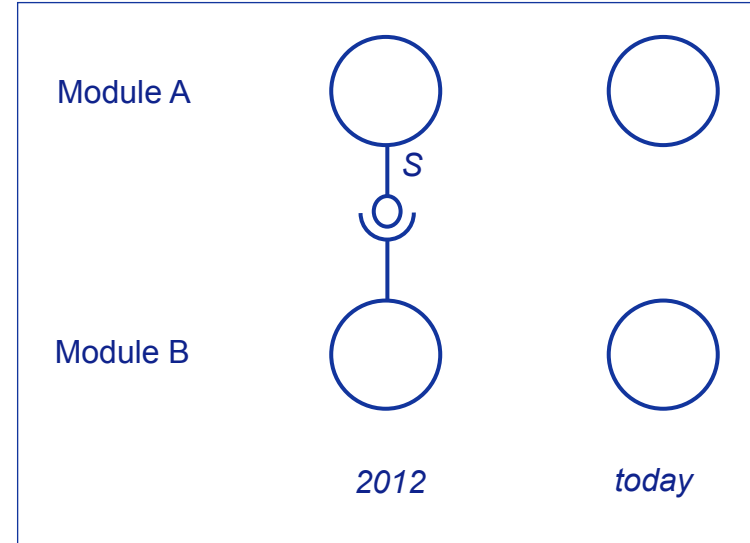

- When upgrading a module, dependencies should still be satisfied.
- Fewer dependencies => easier to upgrade.
- Given a software system, are modules sufficiently **independent** such that they can be **upgraded** easily?

# Upgrade dependencies

New symbol added and used

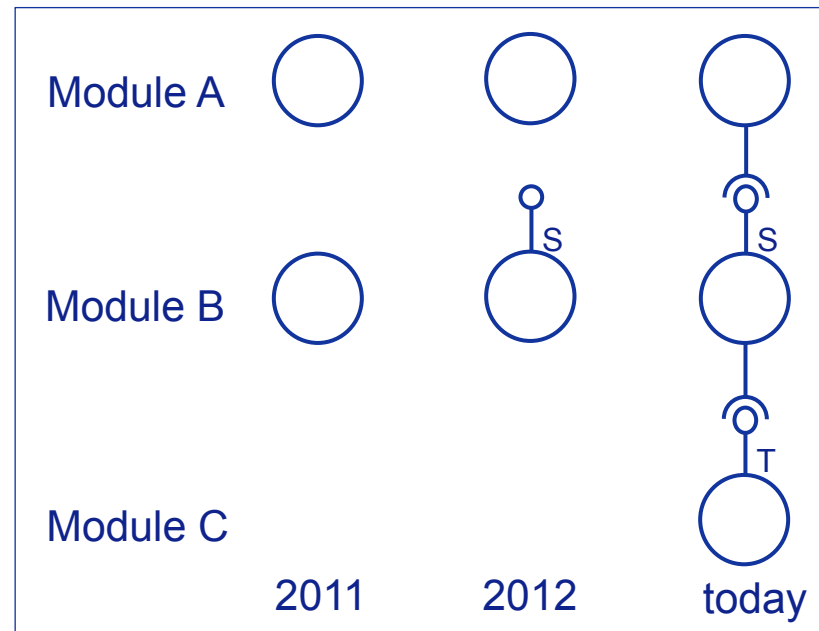

Symbol removed

# Example of upgrade dependencies

Two alternatives for B providing symbol S.

Objective: Choose a **minimal** set of upgrade dependencies (limit impact).

# Approach outline

1. Gather syntactical interface usage data.

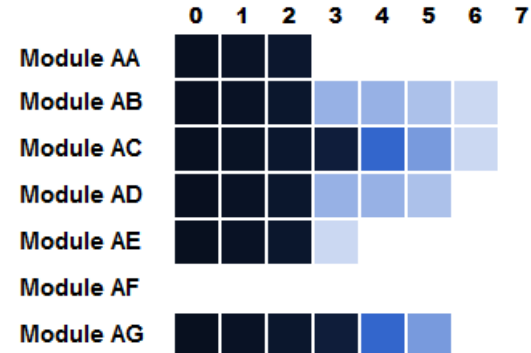

2. Compute for each module  $m$  the number of upgrade dependencies, upgrading  $m$  from version  $i$  to latest version.

3. Visualize results:

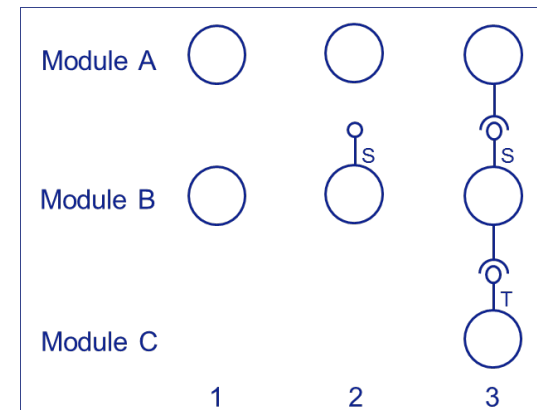

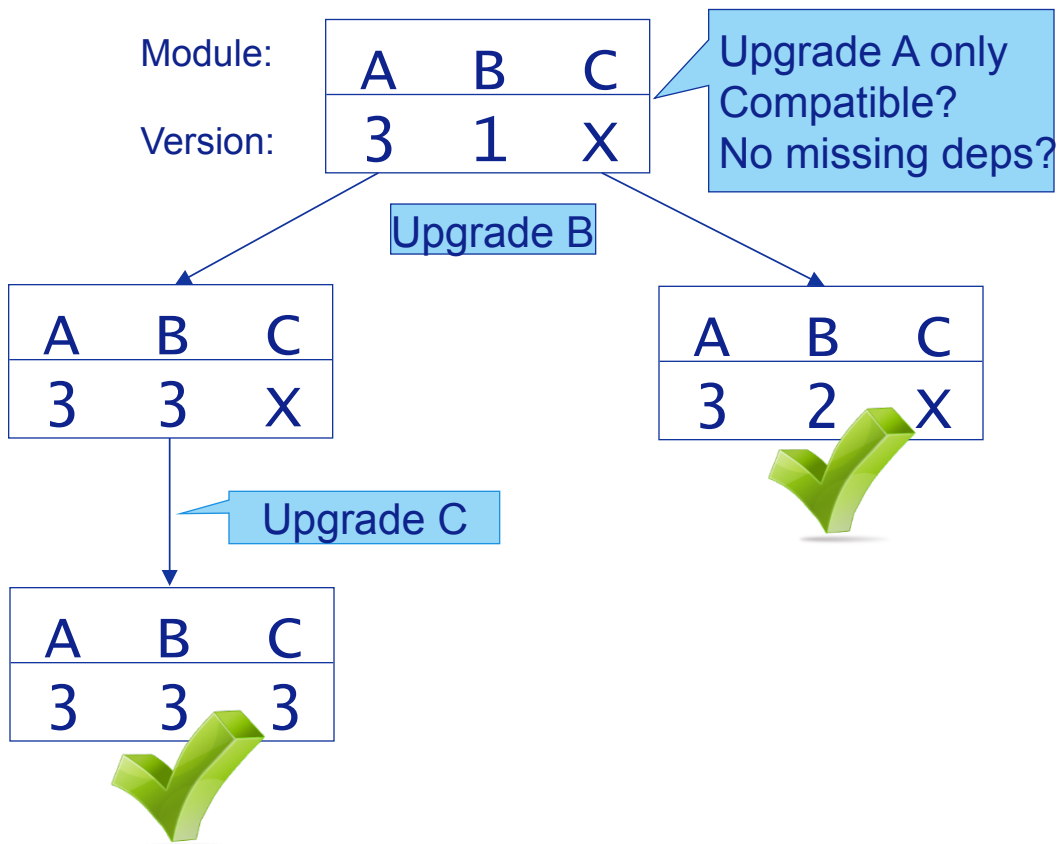

- Heat maps: high level overview
- Dependency graphs: low level details of a particular upgrade

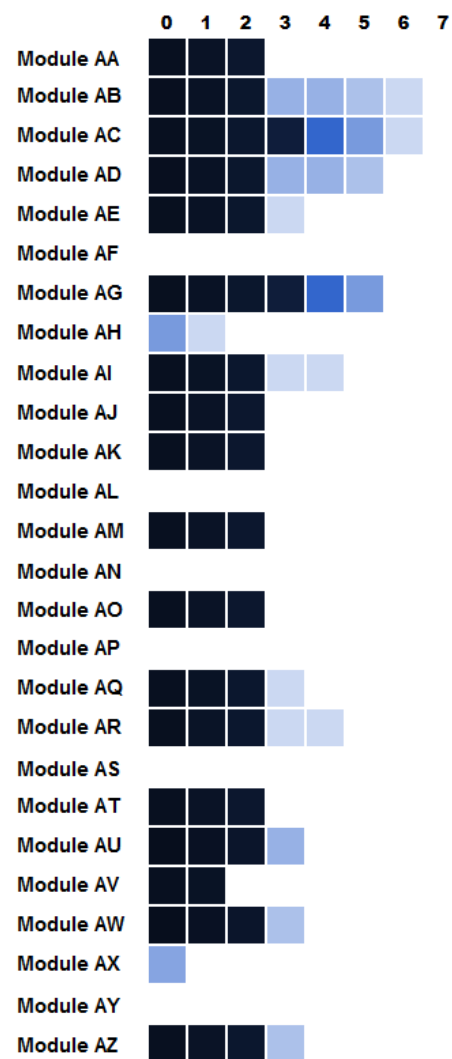

# Find minimal number of upgrade dependencies

Goal: upgrade A from version 1 to 3

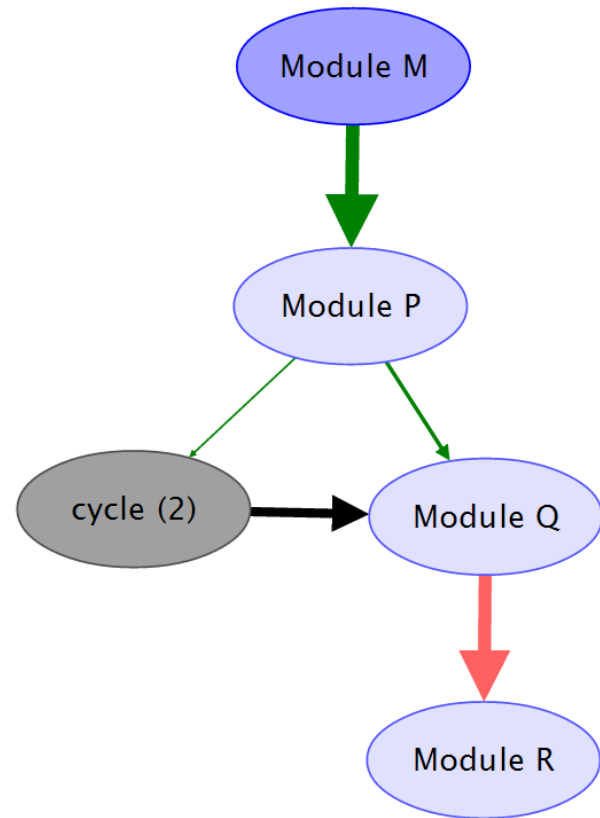

# High level visualization: heat map

- Each cell indicates complexity for each module(rows) from an older version (column) to the latest version.
- Darker means more upgrade dependencies (hence, more complex).

# Low level visualization: upgrade dependency graphs

- Dependency graphs provide more details about a particular upgrade
- **Vertices:** all modules involved with upgrade.
- **Edge** from module  $n_1$  to  $n_2$  iff there is an upgrade dependency from  $n_1$  to  $n_2$ .
  - **Green edge:** upgrade dependency due to symbol addition(s).
  - **Red edge:** upgrade dependency due to symbol removal(s).
  - **Black edge:** green and red combined.
  - **Thickness:** number of symbols.

# Case study performed at ASML Netherlands B.V.

Slide 12

October 15, 2013

- Manufacturer of chip-making equipment.
- Designs, develops and integrates systems to produce semiconductors.
- 1000 software developers
- 40 MLOC
- 327 modules
- 7000 interfaces
- 9 versions of the software analyzed (between Oct. '11 – Jul. '12)

# Result (1)

- Applied approach on software at ASML.
- 327 modules \* 8 versions = **2616 upgrade scenarios**
- Processing time: **16 hours** for all scenarios
  - With limitations on search space.

## Results (2)

- ≤10 upgrade dependencies
- >10 upgrade dependencies

- Upgrade dependencies due to removal of symbols
- What if we ignore the removal of symbols?

# Conclusion

Synchronizing patches is time-consuming and error-prone.

Module-oriented patching: modules should be independent.

Determine upgrade dependencies for each module.

Case study: provided new insights in how modules are related and how to improve future upgrades.
